Package Management

Package Management Overview

- If I had to give *only one reason* why Unix systems are superior to Windows: Package Management.
- Can install almost anything with ease of from your terminal.
- Update to the latest version with one command.
    - No more download the latest installer nonsense!
- Various tools can be installed by installing a *package*.
    - A package contains the files and other instructions to setup a piece of software.
    - Many packages depend on each other.
    - High-level package managers download packages, figure out the dependencies for you, and deal with groups of packages.
    - Low-level managers unpack individual packages, run scripts, and get the software installed correctly.

Many different philosophies

- Monolithic binary packages: one big "app" with everything bundled together
  - docker containers, most windows programs
- Small binary packages: separate common code into independently-installed "libraries"
  - MSI files, Ubuntu, most of linux
- Source-based packages: no installers at all! Compile all your programs
  - language-based package managers, brew, portage
- Benefits to all approaches
  - monolithic binary: fastish install, very independent programs
  - small binary: very fast install, less wasted space
  - source-based: fastest code, smallest install, easy to use open-source

Package Managers in the Wild

- GNU/Linux:
  - Low-level: two general families of *binary packages* exist: `deb`, and `rpm`.
  - High-level package managers you are likely to encounter:
    - Debian/Ubuntu: `apt-get`, `apt`, `aptitude`.
    - SUSE/OpenSUSE: `zypper`.
    - Fedora: `dnf` (Fedora 22+) / `yum`.
    - RHEL/CentOS: `yum` (until they adopt `dnf`).
    - Arch: `pacman`
    - Gentoo: `Portage`, `emerge` (my favorite)

- Mac OSX:
  - Others exist, but the only one you should ever use is `brew`.
  - Don't user others (e.g. `port`), they are outdated / EOSL.

Using Package Managers

- Though the syntax for each package manager is different, the concepts are all the same.
    - This lecture will focus on `apt`, `dnf`, `emerge`, and `brew`.
    - The `dnf` commands are almost entirely interchangeable with `yum`, by design.
    - Note that `brew` is a "special snowflake", more on this later.
- What does your package manager give you? The ability to
    - `install` new packages you do not have.
    - `remove` packages you have installed.
    - `update` installed packages.
    - update the lists to search for files / updates from.
    - view `dependencies` of a given package.
    - a whole lot more!!!

A Note on **update**

- These "subcommands" are by category, not name: **update** is not always called **update**
- The **update** command has importantly different meanings in different package managers.
- Most do **not** default to system (read linux kernel) updates.
    - Fedora does; most others do not.
- It depends on your operating system, and package manager.
    - Know your operating system, and look up what the default behavior is.
- If your program needs a specific version of the linux kernel, you need to be very careful!
    - very, **very** few programs care about your kernel version.

A Note on Names and their Meanings

- Package names sometimes specify architecture:
    - **[**3456x**]86** (e.g. .i386 or .i686 or x86):
        - These are the 32-bit packages.
    - x86_64 or amd64: these are the 64-bit packages.
    - noarch: these are independent of the architecture.
- Ubuntu / fedora often splits packages into smaller pieces:
    - The header files are usually called something like:
        - deb: usually <package>-dev
        - rpm: usually <package>-devel
    - The library you will need to link against:
        - If applicable, lib<package> or something similar.
    - The binaries (executables), often provided by just <package>.
    - Most relevant for C and C++, but also Python and others.
    - Use the search functionality of your package manager.

Example Development Tool Installation

- If I needed to compile and link against `Xrandr` (X.Org X11 libXrandr runtime library) on ubuntu, I would have to install
    - `libxrandr2`: the library.
    - `libxrandr-dev`: the header files.
    - Usually don't explicitly include the architecture (e.g. `.x86_64`), it's inferred
    - If you're getting link errors, try installing explicit 32/64-bit version.
        - just google your error

- Splitting devel files more common for *binary* package managers, less for source-based ones.

System Specific Package Managers

Debian / Ubuntu Package Management (**apt**)

- Installing and uninstalling:
    - Install a package:
      apt install <pkg1> <pkg2> ... <pkgN>
    - Remove a package:
      apt remove <pkg1> <pkg2> ... <pkgN>
    - Only one **pkg** required, but can specify many.
    - "Group" packages are available, but still the same command.
- Updating components:
    - Update lists of packages available: apt update.
        - No arguments, it updates the whole list (even if you give args).
    - Updating currently installed packages: apt upgrade.
        - Specify a **package** name to only update / upgrade that package.
    - Update core (incl. kernel): apt dist-upgrade.
- Searching for packages:
    - Different command: apt-cache search <pkg>

RHEL / Fedora Package Managers (**yum** and **dnf**)

- Installing and uninstalling:
    - Install a package:
      dnf install <pkg1> <pkg2> ... <pkgN>
    - Remove a package:
      dnf remove <pkg1> <pkg2> ... <pkgN>
    - Only one **pkg** required, but can specify many.
    - "Group" packages are available, but different command:
        - dnf groupinstall 'Package Group Name'
- Updating components:
    - Update EVERYTHING: dnf upgrade.
    - **update** exists, but is essentially **upgrade**.
        - Specify a **package** name to only upgrade that package.
    - Updating repository lists: dnf check-update
- Searching for packages:
    - Same command: dnf search <pkg>
- **yum** and **dnf** (Dandified Yum) nearly interchangeable: [2].

Gentoo package manager (**portage** with **emerge**)

- *source-based* package manager: compiles your packages
    - just runs a special **bash** script to compile
    - very, very fine-grained control over dependencies and features
    - use the latest software specialized to your hardware!
- **USE** flags control special "optional" features
    - would be separate packages on ubuntu
    - Want **java** or **emacs** integration? USE="java emacs…"
- Installing, uninstalling, and updating
    - **emerge** package to install
    - **emerge -v --depclean** to remove
        - explicitly checks to ensure other packages don't need it first
    - **emerge -uND @world** to upgrade everything
        - flags are "update", "newuse" (if you turned on a feature), "deep" (also check dependencies for this stuff)

Cautionary Tales

- **WARNING**: if you install package **Y**, which installs **X** as a dependency, and later `remove Y`
  - Sometimes **X** will be removed immediately!
  - Sometimes **X** will be removed during a cleanup operation later
- Solution?
  - Basically, **pay attention to your package manager**.
  - Install packages explicitly that you need
  - Check lists of packages when removing things
- Why does this happen at all?
  - Linux splits things into dependencies: avoids lots of extra copies
  - Side effect: dependencies are *visible* to you; you can use directly
  - In windows: dependencies are *hidden*

OSX Package Management: Install **brew** on your own

- Sitting in class right now with a Mac?

- **DON'T DO THIS IN CLASS**. You will want to make sure you do not have to interrupt the process.

    - Make sure you have the "Command Line Tools" installed.

        - Instructions are on the First Things First Config Page

    - Visit `http://brew.sh/`
    - Copy-paste the given instructions in the terminal *as a regular user (not **root**:).*

- **VERY IMPORTANT**: READ WHAT THE OUTPUT IS!!!! It will tell you to do things, and you *have* to do them. Specifically

    ```
    You should run 'brew doctor' BEFORE you install anything.
    ```

Package Management is a core Philosophy

- Most of what makes a Linux *distribution* is its package manager
- Reflects Distribution's philosophy
    - Ubuntu: "just work" and don't think too hard
    - Fedora: "latest everything" but keep it stable+not too hard
    - Arch: I want to understand how my distro works.
    - Gentoo: I *do* understand how my distro works.

If you're thinking of installing Linux, by the way...

- Ubuntu
  - Benefits: easy install, out-of-the-box setup, common things "just work"
  - Drawbacks: too much magic; system "just work" scripts break if you need to do too many uncommon things and aren't really careful
- Fedora
  - Benefits: still pretty easy to install, lots of good "get started quick" stuff. Good in a VM too
  - Drawbacks: a little less stable; can change deep system things but also not hard to break your system that way.

If you're thinking of installing Linux, by the way...

- Arch
  - Benefits: wealth of knowledge, really helps you understand *why* your system works and what makes it work
  - Drawbacks: limited automagic. Takes real time to set things up, or change important things.
- Gentoo
  - Benefits: similar to Arch, plus the source-based Portage package manager is pure gold. Great if you're doing serious programming/systems work, or if you really need a thing from github that was released last week, or you have a limited environment. Great way to really learn Linux.
  - Drawbacks: absolutely no automagic. Takes real time to set things up, compiling is time-consuming, all the docs think you know what you're doing.

Non-system package managers

OSX Package Management (**brew**)

- Installing and uninstalling:
    - Install a *formula*:
      brew install <fmla1> <fmla2> ... <fmla2>
    - Remove a formula:
      brew uninstall <fmla1> <fmla2> ... <fmlaN>
    - Only one **fmla** required, but can specify many.
    - "Group" packages have no meaning in **brew**.
- Updating components:
    - Update **brew**, all *taps*, and installed formulae listings. This does
      not update the actual software you have installed with **brew**,
      just the definitions: brew update.
    - Update just installed formulae: brew upgrade.
        - Specify a **formula** name to only upgrade that formula.
- Searching for packages:
    - Same command: brew search <formula>

OSX: One of These Kids is Not Like the Others (Part I)

- Safe: confines itself (by default) in `/usr/local/Cellar`:
    - common feature of "non-system" package managers
    - No `sudo`, plays nicely with OSX (e.g. Applications, `python3`).
    - Non-linking by default. If a conflict is detected, it will tell you.
    - **Really important to read what `brew` tells you!!!**
- `brew` is modular. Additional repositories ("*taps*") available:
    - This concept exists for all package managers
- Common taps people use:
    - `brew tap homebrew/science`
        - Various "scientific computing" tools, e.g. `opencv`.
    - `brew tap caskroom/cask`
        - Install `.app` applications! Safe: installs in the "Cellar", symlinks to `~/Applications`, but *now these update with brew all on their own* when you `brew update`!
        - E.g. `brew cask install vlc`

OSX: One of These Kids is Not Like the Others (Part II)

- **brew** installs *formulas*.
  - A **ruby** script that provides rules for where to download something from / how to compile it. Similar concept to **portage**'s bash files
- Sometimes the packager creates a "Bottle":
  - If a bottle for your version of OSX exists, you don't have to compile locally.
  - The bottle just gets *downloaded* and then "*poured*".
- Otherwise, **brew** downloads the source and compiles locally.
- Though more time consuming, can be quite convenient!
  - `brew options opencv`
  - `brew install --with-cuda --c++11 opencv`
  - It really really really is magical. Just like USE flags in Gentoo!
  - `brew reinstall --with-missed-option formula`

OSX: One of These Kids is Not Like the Others (Part III)

- Reiteration: pay attention to **brew** and what it says. Seriously.
- Example: after installing **opencv**, it tells me:

```
==> Caveats
Python modules have been installed and Homebrews site-packages
is not in your Python sys.path, so you will not be able to
import the modules this formula installed. If you plan to
develop with these modules, please run:

mkdir -p /Users/sven/.local/lib/python2.7/site-packages
echo 'import site; site.addsitedir(                      \
    "/usr/local/lib/python2.7/site-packages")' >> \
    /Users/sven/.local/lib/python2.7/site-packages/homebrew.pth
```

- **brew** gives copy-paste format, above is just so you can read.
- I want to use **opencv** in **Python**, so I do what **brew** tells me.

Language-specific package management

- Modern programming language environments have their own package managers
    - Haskell: `cabal`
    - Ocaml: `opam`
    - Python: `conda`/`pip`/`pip3`
    - Ruby: `bundler` / `gem`
    - Rust: `cargo`
- Works basically exactly like `brew`
    - separate, user-specific install directory
    - preferred to system packages but does not replace them
- Be careful when using these!
    - system packages are not preferred, but sometimes get used anyway
    - when languages rely on external packages, things get really hairy

Other Managers

Like What?

- There are so many package managers out there for different things, too many to list them all!
- Ruby: `gem`
- Anaconda Python: `conda`
- Python: `pip`
- Python: `easy_install` (but really, just use `pip`)
- Python3: `pip3`
- LaTeX: `tlmgr` (uses the CTAN database)
    - Must install TeX from source to get `tlmgr`
- Perl: `cpan`
- Sublime Text: `Package Control`
- Many many others...

Like How?

- Some notes and warnings about Python package management.
- Notes:
    - If you want X in Python 2 **and** 3:
        - `pip install X` *and* `pip3 install X`
    - OSX Specifically: advise only using **brew** or Anaconda Python. The system Python can get really damaged if you modify it, you are better off leaving it alone.
    - So even if you want to use **python2** on Mac, I strongly encourage you to install it with **brew**.
- Warnings:
    - Don't mix **easy_install** and **pip**. Choose one, stick with it.
        - But the internet told me if I want **pip** on Mac, I should `easy_install pip`
        - NO! Because this **pip** will modify your **system** python, USE BREW.
    - Don't mix **pip** with **conda**. If you have Anaconda python, just stick to using **conda**.
